Abstract: Background — Non-specific low back pain (LBP) has direct impact on life quality, active days at work and health care costs. The aim of this study was to examine the correlation between lumbar lordosis (LL), LBP intensity and low back pain disability index (LBPDI).

Material and Methods — This cross-sectional study was conducted among 52 dentists (56% male and 44% female). Dentists’ low back pain intensity and low back disability index were examined with the self-administered visual analog scale and modified Oswestry questionnaire, respectively. LL was calculated using flexible ruler based on Youda’s method.

Results — The mean LBP and LBPDI were equal to 61.0±23.7 and 31.4±11.8, respectively. In addition, a significant relationship between LBP, sex and BMI as well as between LBPDI, work experience and BMI were found (P≤0.001). There was a strong significant positive correlation between LBP and LBPDI (r=0.937). Additionally, the results showed no significant correlation between LBP, LBPDI and LL (P>0.05).

Conclusion — The results suggest that despite the lack of correlation between LBP intensity and LBPDI with LL, male sex, work experience and BMI are the important risk factors associated with LBP and LBPDI in dentists and thus should be taken into consideration for preventative and intervention strategies.

Keywords: disability index, low back pain, lumbar lordosis.

criteria for inclusion in the study were the lack of a history of spinal surgery and traumatic orthopedic problems such as acute back and nerve problems, inflammatory diseases such as Ankylosing spondylitis involving the spine, congenital diseases such as scoliosis and hemi vertebrae. Due to the inclusion criteria, 2 dentists were excluded from the study. LBP intensity and disability indices were evaluated by a visual analogue discomfort scale and Oswestry questionnaire. LL was measured using a flexible ruler based on Youda’s method [10]. All participants agreed to participate in this study, read and signed an informed consent form approved by the ethics committee of Shahid Beheshti University of Medical sciences. Furthermore, we measured body mass index (BMI), which according to the health communities [11] is a measure of body fat calculated by person’s weight in kilograms divided by the square of height in meters.

Visual analogue discomfort scale

To indicate the level of discomfort the subjects were asked to mark degree of subjective discomfort on a horizontal line of 100 mm long. Subjective intensity of discomfort was recorded numerically from zero (without discomfort) to 100 (severe discomfort) using a millimetre ruler. The advantages of this tool include its ease of management, sensitivity and amenability to statistical analysis [12].

Oswestry disability index

A modified version of the Oswestry’s disability index self-administered questionnaire with 10 items was used to examine the degree of physical disability resulted from chronic LBP and its effect on the daily activities of the person. In each section, the degree of physical disability was scored from zero (desirable performance and without pain) to five (disability in performance due to severe pain). Finally, the physical disability degree was classified as mild (0 to 20%), moderate (21 to 40%), severe (41 to 60%), disabling (61 to 80%) and severely disabling (81 to 100%) [9].

Lumbar lordosis measurement

LL was measured using a flexible ruler (Ghamat Pooyan Co., Iran) based on Youda’s method [10, 13, 14]. We used a flexible ruler for the measurement of LL, according to the distance of the spinal process of two reference bones, i.e. T12 and S2. The Hoppenfeld method was employed to find the two bone landmarks [15]. Finally, the angle between these two bone landmarks (T12 and S2) was calculated and reported as LL.

Statistical analysis

Statistical data analysis was done using SPSS (version 22.0, IBM Corporation, Armonk, NY, USA). Kolmogorov-Smirnov test was used to determine the normality of the data. Independent samples test was used to evaluate the mean differences of LBP, LBPDl and LL between marital status and sex groups, while the Pearson and Spearman correlation coefficients were employed to test the correlation between LBP, LBPDl and LL with age, work experience and body mass index (BMI). Correlation of BMI, sex, age and work experience variables with the LBP, LBPDl and LL was analysed using linear regression models. The confidence level was considered as P-value ≤0.05.

Results

The characteristics of the participants are highlighted in Table 1. Fifty-six and 44 percent of the subjects were female and male, respectively; also 34 and 66 percent of the participants were single and married, respectively. In this study, 30, 58 and 12 percent of the participants were classified in the normal, overweight and obese classes. Therefore, the highest frequency of body mass index of people belonged to the normal class.

The mean disability caused by LBP and LBPDl were equal to 61±23.7 and 31.4±11.8, respectively; LBP and LBPDl in 32 and 42 percent of participants were classified as disabling and moderate classes, respectively. In addition, there was a strong significant positive correlation between LBP and LBPDl. Distribution of LBP and LBPDl among the dentists is presented in Table 2.

The correlation between LBP, LBPDl and LL with dentist’s characteristics are shown in Table 3. A significant relationship was reported between LBP, sex and BMI; and also between LBPDl, work experience and BMI. There was a significant relationship between lumbar curvature angle and sex, marriage status and age.

The results of the linear regression analyses for LBP, LBPDl and LL are reported in Table 4. Among the total participants, being male and increase of BMI were significant risk factors for LBP, while in the case of LBPDl, work experience and BMI were reported as significant risk factors. As shown by the linear regression equation, female sex and increase of age led to an augmentation of the LL (Adjusted R²=0.997; P=0.001). Furthermore, male sex and increase of BMI resulted in an increase of the LBP (Adjusted R²=0.462; P=0.001). Concordantly, increase of work experience and BMI caused an increase of the LBPDl (Adjusted R²=0.377; P=0.001). At the end, the results showed no significant correlation between LBPDl and LL (P>0.05).

Discussion

The aim of this study was to test the hypotheses that LBP intensity and LBPDl are related to LL in dentists. We reported no significant correlation between LL in dentists with LBP and LBPDl. Our findings are aligned with the results of Evcik and Yucel [16] that reported no statistical correlation between LL and chronic LBP patients. In addition, a systematic review and meta-analysis by Laird et al. [17] showed no significant difference of lumbar lordotic curvature between subjects with and those without LBP. On the other hand, Christopher et al. reported a significant positive relationship between LBP intensity and the degree of lordosis [5]; also in a systematic review and meta-analysis consisting of 13 studies including 796 and 927 patients with and without LBP respectively Chun et al. [6] reported that patients with LBP have smaller lumbar lordotic angle rather than patients without LBP. Although in our study a significant differences in age, gender, marital status and lumbar lordotic angle were observed, linear regression equation showed that just female sex and increase of age could lead to an increase of the LL. Therefore, our findings are aligned with the results of Evcik and Yucel [16] that showed females had greater lumbosacral angle.

* Multiple linear regression model.

In a previous study, we reported that 60% of dentists had moderate LBPDI [18], similar to the data by Ilyas and Dharmaji [19] who reported 74.4% and 25.6% of mild to moderate LBPDI among the subjects. While we observed only 32% of disabling pain, however, it should be noted that although in subjects with moderate LBPDI, personal care and sleep are not affected greatly, they work experience more pain while sitting, standing and lifting, and thus traveling and social life become difficult for them which could possibly lead to missing work.

Here, a significant positive relationship was observed between LBP, sex and BMI similarly between LBPDI, work experience and BMI. This was especially evident in the case of BMI. Our finding are aligned with the results of our previous study [18] and Youdas et al. [20] studies, that reported higher risk of LBP in women and men with a higher BMI.

The high prevalence of LBP among dentists related to the posture and movements in their daily work have been reported in the previous studies [2, 18, 21]. In a sitting position, lumbar lordotic curvature drops and prevents LBP. Also during standing position, 40-70% of back-healthy people reported LBP symptoms [22]. Therefore change of the working positions and thus involving different muscle groups, for example rotating the working positions from standing to sitting and vice versa can be an effective strategy [23], since those dentists who were working only in the sitting or standing positions had more LBP than those with rotating standing and sitting positions [24].

Conclusion

Despite the lack of correlation between LBP intensity and LBPDI with LL, male sex, work experience and BMI were identified as important occupational or individual factors associated with LBP and LBPDI in dentists. Thus, paying attention to ergonomic issues in dentist’s workplace such as use of ergonomic equipment and rest schedules, especially with respect to increase of work experience as well as male sex, and furthermore balance of the BMI by means of diet and physical exercise should be taken into consideration. The small sample size and the study conduction in one dentistry clinic were the limitations of this study; therefore, it is better to conduct similar studies in larger and different populations.

Ethical approval

All procedures performed in studies involving human participants were in accordance with the ethical student research committee of Shahid Beheshti University of Medical Sciences, Tehran, Iran and with the principles of the declaration of Helsinki (1964) and its later amendments or comparable ethical standards.

Conflict of interest

The authors declare that there are no conflicts of interests regarding the publication of this article.

Acknowledgments

This study was related to the project NO. 1396/50176 from Student Research Committee, Shahid Beheshti University of Medical Sciences, Tehran, Iran. We appreciate the “Student Research Committee” and “Research & Technology Chancellor” in Shahid Beheshti University of Medical Sciences for their financial support of this study.
